ABSTRACT

With the availability of large datasets in a variety of scientific and commercial domains, data mining has emerged as an important area within the last decade. Data mining techniques focus on finding novel and useful patterns or models from large datasets. Because of the volume of the data to be analyzed, the amount of computation involved, and the need for rapid or even interactive analysis, data mining applications require the use of parallel machines.

We believe that parallel compilation technology can be used for providing high-level language support for carrying out data mining implementations. Our study of a variety of popular data mining techniques has shown that they can be parallelized in a similar fashion. In our previous work, we have developed a middleware system that exploits this similarity to support distributed memory parallelization and execution on disk-resident datasets.

This paper focuses on developing a data parallel language interface for using our middleware's functionality. We use a data parallel dialect of Java and show that it is well suited for data mining algorithms. Compiler techniques for translating this dialect to a middleware specification are presented. The most significant of these is a new technique for extracting a global reduction function from a data parallel loop.

We present a detailed experimental evaluation of our compiler using apriori association mining, k-means clustering, and k-nearest neighbor classifiers. Our experimental results show that: 1) compiler generated parallel data mining codes achieve high speedups in a cluster environment, 2) the performance of compiler generated codes is quite close to the performance of manually written codes, and 3) simple additional optimizations like inlining can further reduce the gap between compiled and manual codes.

1. INTRODUCTION

Analysis of large datasets for extracting novel and useful models or patterns, also referred to as *data mining*, has emerged as an important area within the last decade [16]. Because of the volume of data analyzed, the amount of computation involved, and the need for rapid or even interactive response, data mining tasks require the use of parallel machines and careful management of the memory hierarchy.

This paper focuses on the use of compiler technology for offering high-level support for implementing data mining algorithms. In our previous work, we have developed a middleware for rapidly developing data mining implementations [20, 19, 21]. The middleware exploits the similarity between the algorithms to offer a runtime support and a programming interface. In this paper, we present compiler techniques to translate a high-level code to a middleware specification. The particular language that we will use is a data parallel dialect of Java. The main new analysis required is for extracting a global reduction function from a data parallel loop. In addition, a number of other interesting issues arise in handling data mining codes and generating middleware code, and are addressed in our research.

We have implemented our techniques using the Titanium infrastructure from Berkeley [29]. We present experimental results from apriori association mining, k-means clustering, and k-nearest neighbor classifier. We have experimented with disk-resident datasets for each of these codes. Our experimental results show that 1) compiler generated parallel data mining codes achieve high speedups in a cluster environment, 2) the performance of compiler generated codes is quite close to the performance of manually written codes, and 3) simple additional optimizations like inlining can further reduce the gap in performance of compiled and manual codes.

The rest of the paper is organized as follows. The language dialect we use is presented in Section 2. The interface and functionality of our middleware is described in Section 3. Our compiler techniques are presented in Section 4. Experimental evaluation of our prototype compiler is the topic of Section 5. We compare our work with related research efforts in Section 6 and conclude in Section 7.

2. DATA PARALLEL LANGUAGE SUPPORT

The structure of the various data mining algorithms we have studied, including those for association mining, clustering, nearest neighbor searches, bayesian networks and decision tree construction, can be viewed as comprising *generalized reduction operations* [17]. Processing for generalized reductions consists of three main steps: (1) retrieving data items of interest, (2) applying application-specific transformation operations on the retrieved input items, and, (3) mapping the input items to output items and aggregating all the input items that map to the same output data item. Most importantly, aggregation operations involve *commutative* and *associative* operations, i.e., the correctness of the output data values does not depend on the order input data items are aggregated. Such a common structure makes data mining algorithms a suitable target for a compilation framework.

We now describe a data parallel dialect of Java that can be used

Figure 1: k-means clustering Expressed in Data Parallel Java

for expressing parallel algorithms for common data mining tasks. Though we propose to use a dialect of Java as the source language for the compiler, the techniques we will be developing will be largely independent of Java and will also be applicable to suitable extensions of other languages, such as C or C++.

We use three main directives in our data parallel dialect. These are for specifying a multi-dimensional collections of objects, a parallel for loop, and a reduction interface. The first two have been commonly used in other object-oriented parallel systems like Titanium [29], HPC++ [6], and Concurrent Aggregates [11]. The concept of reduction interface is, to the best of our knowledge, novel to our approach. The choice of these directives is motivated by the structure of data mining algorithms we described earlier.

Rectdomain: A rectdomain is a collection of objects of the same type such that each object in the collection has a *coordinate* associated with it, and this coordinate belongs to a pre-specified rectilinear section.

Foreach loop: A foreach loop iterates over objects in a rectdomain, and has the property that the order of iterations does not influence the result of the associated computations.

Reduction Interface: Any object of any class implementing the reduction interface acts as a *reduction variable* [17]. The semantics of a reduction variable are analogous to those used in version 2.0 of High Performance Fortran (HPF-2) [17]. A reduction variable has the property that it can only be updated inside a *foreach* loop by a series of operations that are associative and commutative. Furthermore, the intermediate value of the reduction variable may not be used within the loop, except for self-updates.

Another interface we use is *Disk-resident*. Any class whose objects are either read or written from disks must implement this interface. For any class which implements the reduction interface, or represents objects that are disk-resident, we expect a constructor function that can read the object from a string. In the case of a class that implements the reduction interface, such constructor function is used for facilitating interprocessor communication. Specifically, the code for the constructor function is used for generating code for copying an object to a message buffer and copying a message buffer to an object. Similarly, for any dataset which is either read or written to disks, the constructor function is used to generate code that reads or writes the object.

The data parallel Java code for k-means clustering is shown in Figure 1. k is the number of clusters that need to be computed. An object of the class `KmPoint` represents a three-dimensional point. The variable `Input` represents a one-dimensional array of points, which is the input to the algorithm. In each iteration of the `foreach` loop, one point is processed and the cluster whose center is closest to the point is determined. The function `Assign` accumulates coordinates of all points that are found to be closest to the center of a given cluster. It also increments the count of the number of points that have been found to be closest to the center of a given cluster. The function `Finalize` is called after the `foreach` loop. It determines the new coordinates of the center of a cluster, based upon the points that have been assigned to the cluster. The details of the test for termination condition are not shown here.

3. MIDDLEWARE INTERFACE AND PARALLELIZATION SUPPORT

Our compiler heavily uses our middleware system for distributed memory parallelization and I/O optimizations in processing disk-resident datasets. The middleware's functionality and interface are described in this section.

0-7695-1926-1/03/$17.00 (C) 2003 IEEE
Proceedings of the International Parallel and Distributed Processing Symposium (IPDPS'03)

The middleware interface exploits the similarity among parallel versions of data mining algorithms. A programmer using the middleware directly needs to write the following functions. Most of these functions can be easily extracted from a sequential version that processes main memory resident datasets.

Subset of Data to be Processed: In many case, only a subset of the available data needs to be analyzed for a given task. For example, while creating associations rules from customer purchase record at a grocery store, we may be interested in processing records obtained in certain months, or for customers in a certain age group, etc.

Local Reductions: The data instances owned by a processor and belonging to the subset specified are read. A local reduction function specifies how, after processing one data instance, a *reduction object* (declared by the programmer), is updated. The result of this processing must be independent of the order in which data instances are processed on each processor. The order in which data instances are read from the disks is determined by the runtime system. The reduction object is maintained in the main memory.

Global Reductions: The reduction objects on all processors are combined using a global reduction function. MPI calls for handling the communication are made by the runtime system. However, functions for copying the reduction object to a buffer and from a buffer to the reduction object are expected as part of the middleware interface.

Iterator: Parallel implementations of the applications we target comprise one or more distinct sets of local and global reduction functions, which are be invoked in an iterative fashion. An iterator function contains the loop that invokes local and global reduction functions.

The middleware support for distributed memory parallelization is relatively simple because of the structure of the applications it targets. After data has been distributed between different nodes, each node can execute local reduction functions on data items it owns. After each invocation of local reduction function, local copies of reduction objects on each node are broadcasted to all other nodes, and local copies of reduction objects from all other nodes are received on each node. This communication is facilitated by the middleware. After the communication phase, global reduction function is invoked on each node. The result of global reduction is then broadcasted to all processors.

Our middleware's support for I/O optimizations for processing disk-resident datasets is based upon an earlier system called Active Data Repository (ADR), which was developed for scientific data intensive applications [9, 8].

4. COMPILER TECHNIQUES

We now present compilation techniques for translating a data mining code written in the data parallel dialect to a middleware specification.

In generating the code for the middleware interface, the compiler needs to: 1) Generate an *Iterator* function that invokes local and global reduction functions. 2) For each data parallel loop that updates a reduction object, generate a) the specification of the subset of the data processed in that loop, b) the local reduction function, c) the global reduction function, and d) functions for copying reduction object to and from message buffers.

Conceptually, the most difficult problem is extracting the global reduction function from the body of the data parallel loop. Here, we describe our solution towards this problem.

4.1 Global Reduction Analysis

Consider the reduction objects O and $O1$ computed by two processors after their local reduction phase. We need a function f to update O with the values computed in $O1$, i.e., to perform the computation $O = f(O, O1)$.

The algorithm we have developed is presented in Figure 2. Our algorithm can handle significantly more complicated reduction functions than the previous work in this area [5, 14, 15, 24]. To explain the different cases that the algorithm handles, we use three examples, from k-means clustering, apriori association mining, and k-nearest neighbor search, which are shown in Figures 1, 3, and 4, respectively.

The algorithm is divided into three phases. The first phase is data dependence analysis, the second phase is control dependence analysis, and the final phase is code generation. Any expression or predicate whose value remains unchanged across iterations of the data parallel loop is considered a *loop constant* expression or predicate. Note that the value of such an expression can be different over different invocations of the loop.

Consider the body of the loop that processes an element e and updates a reduction object O. Consider any statement in this code that updates a data member of O. If this statement includes any temporary variables that are defined in the loop body itself, we perform forward substitution and replace these temporary variables. After such forward substitution, the update to the data member can be classified as being one of the following: a) assignment to the value of another data member of the reduction object, or an expression involving one or more other data members, and loop constants, b) assignment to $g(e)$, where the g does not involve any members of the reduction object O, c) update using a commutative and associative operator. op, such that the data member $O.x$ is updated as $O.x = O.x\ op\ g(e)$, where the function g does not involve any members of the reduction object O, or d) any other expression.

Updates of type (a) can arise in a function like average, where sum, count, and average are the three data members of the reduction object. After computing sum and count, average is computed by dividing sum by count, which is an expression involving other data members. An example of a local reduction function with an update of type (b) is k-nearest neighbors (Figure 4). The reduction object in this code comprises the coordinates of k-nearest neighbors to the given point. As a new point is processed, it may be inserted as one of the nearest neighbors. Updates of type (c) arise frequently in loop bodies of codes that perform reduction computations. Examples include updates to sum and count fields in a function like average, and updates in k-means clustering and apriori association mining (Figure 1 and 3, respectively).

After data dependence analysis, the set of statements which update a data member of the reduction object is denoted by S. The next phase of the algorithm classifies control dependence to any statement in the set S. We consider two types of control dependence, loop constant and non-loop constant.

The final and the major part of the algorithm is actual code generation. Statements in the set S are treated differently based upon both the type of assignment and control dependence.

Consider any statement with an assignment of type (c). We replace the statement $O.x = O.x\ op\ g(e)$ by a statement of form $O.x = O.x\ op\ O1.x$, i.e. the values aggregated are part of the two reduction objects are combined using the same associative and commutative operator. As an example, look at the assignments to `meanx1[i]`, `meanx2[i]`, `meanx3[i]`, and `count[i]` as part of the function `Assign` in Figure 1. In this case, simple symbolic analysis can determine that i can represent values between 0 and $k - 1$. In other words, $O.x$ can represent one of many

If a statement belonging to $S(r)$ is dependent upon a statement in $S(t)$, $r \neq t$, *exit()*
For each such set $S(r)$
  Insert a loop in which $O1.x'$ iterates over r around all statements in $S(r)$
Remove all statements that no statement in S is data or control dependent on

Figure 2: Algorithm for Synthesizing Global Reduction Function from the Body of Data Parallel Loop

data members of the reduction object. When processing an element e, the actual data member that are incremented depends upon the element. However, in combining two local reduction objects, we simply need to add corresponding `meanx1[i]`, `meanx2[i]`, `meanx3[i]`, and `count[i]`. Therefore, we insert a loop that iterates over the range of i. We also remove any control predicates that are not loop constant. If there is any loop constant control predicate, it needs to be maintained in the global reduction code. An example of such a predicate will be a conditional for determining whether to compute maximum or minimums during a particular invocation of the loop.

A similar situation arises in apriori association mining (Figure 3). The element or transaction analyzed by the loop body is a list of items. A prefix tree maintains sets of items that can occur with a high frequency. The list of transactions is matched against these sets of items and the count associated with a set is incremented when a match is found. The loop body involves complicated control flow. However, the only update to a reduction element occurs in the statement `vect[offset+i] += 1`. The global reduction code, therefore, simply iterates over the different elements of the array `vect` and adds the corresponding elements.

Next, we consider a statement of type (b). As a concrete example, consider the assignment of `kpoint.x1` to `x1[i+1]` in the loop body shown in Figure 4. Again, simple symbolic analysis can determine that the expression $i + 1$ can range between 0 and $k - 1$. We replace this assignment by the assignment `x1[i + 1] = buf.x1[j]`, where j ranges between 0 and $k-1$. Assignments to `x2`, `x3`, and `distance` are processed similarly.

Note that if the loop body includes a statement of type (a), we leave it unchanged.

For statement of both type (a) and (b), we further consider control dependence on non-loop constants. Suppose any statement of type (a) or (b) is control dependent upon a predicate that involves a field l of the input element. We further check if a function $h(l)$ involving this field is assigned to a data member of the reduction object. An example of such control dependence arises in the k-nearest neighbor code. The variable `dis` is computed from the input element and is assigned to the data member `distance`. In such cases, we replace the occurrence of l in the control predicate by $h^{-1}(O1.x')$, where x' ranges over all fields to which $h(l)$ can be assigned. In our example, we replace `dis` by `buf.distance[j]`, with j ranging from 0 to $k - 1$.

If a statement of type (a) or (b) is control dependent upon a field l that is not assigned to the reduction object, we remove such conditional. An example will be if a field of the input element determines whether the data is valid and needs to be processed further. Such a conditional is not required in combining results from local reductions.

```
int cnt = t.cnt;
while (--cnt >= 0) {
  i = t.iids[j] - p.offs;
  if (i < 0) continue;
  if (i >= p.size) return ;
  if ((offset= t.cnt - p.countvector) >= p.upper_used) {
    vect[offset+i] += 1;
  }
  if ( p.chcnt <= 0) continue;
  i += p.offs - p.ID(tree.children[0]);
  if ((i < 0) || (i >= p.chcnt)) continue;
  if (p.children[i] != null)
    LocalReduc( t , p.children[i]);
}

        && (i >= 0)) {
      if(i > 0) {
        x1[i] = x1[i - 1];
        x2[i] = x2[i - 1];
        x3[i] = x3[i - 1];
        distance[i] = distance[i - 1];
      }
      i = i - 1;
    }
    if(i < k-1) {
      x1[i + 1] = buf.x1[j];
      x2[i + 1] = buf.x2[j];
      x3[i + 1] = buf.x3[j];
      distance[i + 1] = buf.distance[j];
    }
  }
}
```

Figure 4: Loop Body (left) and Global Reduction Function (right) for k-nearest neighbors

In the k-nearest neighbor example, we get several expressions that involve a variable j that ranges from 0 to $k-1$. Moreover, the statements involving `buf.x1[j1]`, `buf.x2[j]`, and `buf.x3[j]` are control dependent upon the predicate involving `buf.distance[j]`. For a range r, we compute the set $S(r)$ that includes the statements that are data or control dependent upon a $O1.x'$, where x' has the range r. In generating the code, we insert a single loop that iterates over the range r around these statements.

Two potential complications can arise that our algorithm cannot currently handle. First, a statement belonging to a set $S(r)$ may be dependent upon a statement belonging to the set $S(t)$, $r \neq t$. Second, a single statement may belong to two distinct sets. Our algorithm cannot handle either of these cases. Such cases, however, did not arise in any codes we examined.

5. EXPERIMENTAL RESULTS

We have implemented a prototype compiler incorporating the techniques we have described in this paper. We used the Titanium front-end developed at Berkeley [29]. In this section, we evaluate the compiler using three important data mining algorithms, k-means clustering, apriori association mining, and k-nearest neighbor classifier.

The manually programmed versions we used for our experiments were previously used to evaluate the middleware [20, 19]. The experiments have been conducted on a cluster of workstations. We used 8 Sun Microsystem Ultra Enterprise 450's, with 250MHz Ultra-II processors. Each node has 1 GB of main memory which is 4-way interleaved. Each node has a 4 GB system disk and a 18 GB data disk. The data disks are Seagate-ST318275LC with 7200 rotations per minute and 6.9 milli-second seek time. The nodes are connected by a Myrinet switch with model number M2M-OCT-SW8.

5.1 Results from k-means Clustering

The first data mining algorithm we focus on is k-means clustering. The algorithm is parameterized with the value of k (i.e., the number of clusters computed) and the size of the dataset. We used 3 and 100 as the values of k and two datasets, with the size of 1 GB and 2 GB, respectively.

Experimental results from 1 GB dataset and $k = 3$ are presented in Figure 5. The first two versions shown in the figure are compiler generated (`comp`) and manually programmed (`manual`). The rela-

0-7695-1926-1/03/$17.00 (C) 2003 IEEE
Proceedings of the International Parallel and Distributed Processing Symposium (IPDPS'03)

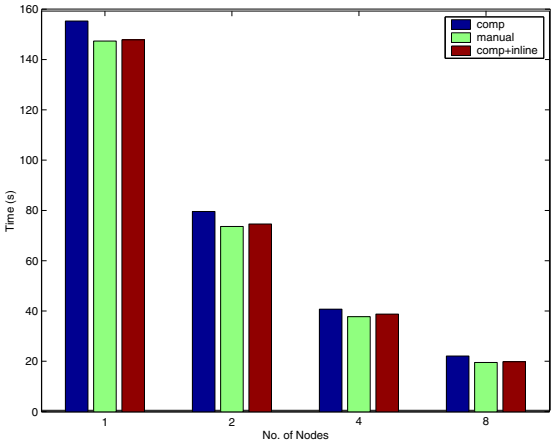

Figure 5: Performance of k-means clustering: k = 3, 1 GB Dataset

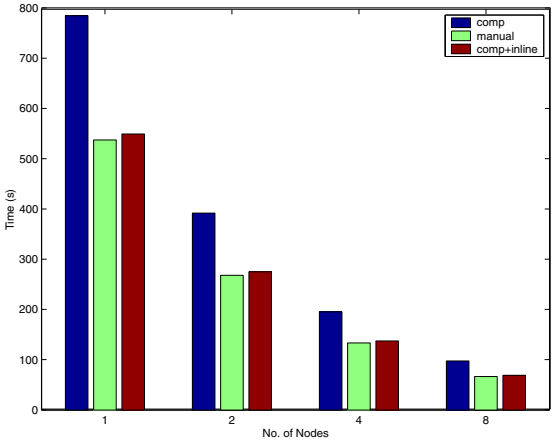

Figure 6: Performance of k-means clustering: k = 100, 1 GB Dataset

tive speedups obtained by the compiler generated version are 1.95, 3.81, and 7.0 on 2, 4, and 8 nodes, respectively. The difference between the compiler and manual versions is less than 10% on 1, 2, and 4 nodes, and 13% on 8 nodes.

We carefully analyzed the reasons for performance differences between the compiler and manual versions. Almost all of the difference comes because the *distance* function invoked inside the inner loop is inlined in the manual version and not in the compiler version. Though such inlining is commonly performed by machine-level compilers, it is was not performed by the `g++` compiler that was used. We created another version, `comp+inline`, in which call to this function is manually inlined. The difference between `manual` and `comp+inline` versions is within 2%.

Figure 6 shows experimental results from the same dataset, but with $k = 100$. The *distance* function is invoked more frequently with the larger value of k. Therefore, there is a greater difference in the performance of `comp` and `manual` versions. After applying inlining manually, the difference reduces to within 3%. Because there is more computation between two phases of communication, the speedups are higher. All three versions have perfect linear relative speedups on 2, 4, and 8 nodes.

Figure 7 shows experimental results from the 2 GB dataset with $k = 100$. The speedups and relative performance of the three ver-

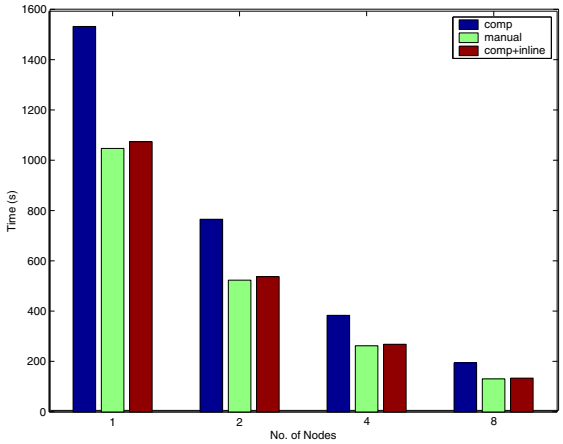

Figure 7: Performance of k-means clustering: k = 100, 2 GB Dataset

sions are almost identical to the ones seen with 1 GB dataset. A comparison of the results from 1 GB and 2 GB datasets shows that as the dataset size is increased, the execution times increase in a linear fashion. As the dataset does not fit in the main memory, the execution times do not increase in a super-linear fashion.

5.2 Results from Apriori Association Mining

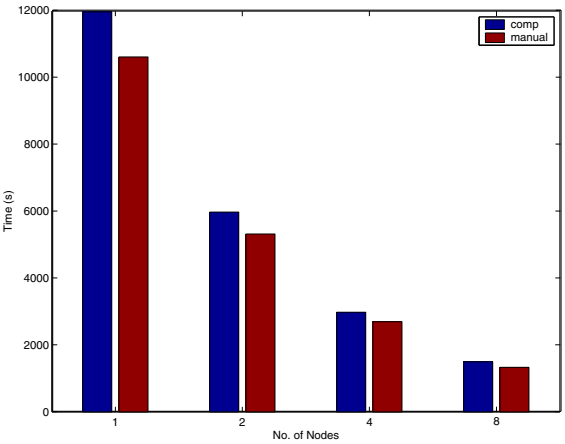

Figure 8: Performance of Apriori Association Mining: 3 GB Dataset, 7 iterations

The second data mining algorithm we used for evaluating the compiler is apriori association mining.

Figure 8 presents experimental results from a 3 GB dataset. Support level of .25% and confidence level of 90% were used in our experiments. For this dataset and these parameters, 7 iterations were required to obtain final results. Figure 8 shows execution times for 7 iterations. On 8 nodes, `comp` and `manual` versions have relative speedups of 7.98 and 7.97, respectively. The difference in performance is between 10% and 13% in all cases.

Again, we analyzed the reasons for difference in the performance. The compiler generated version performed extra copying of the input data, whereas the manual version analyzed data directly from the read buffer. To further analyze these differences, we experimented with a smaller dataset. Figures 9 and 10 show execution times of compiler and manual versions for the first and the first two

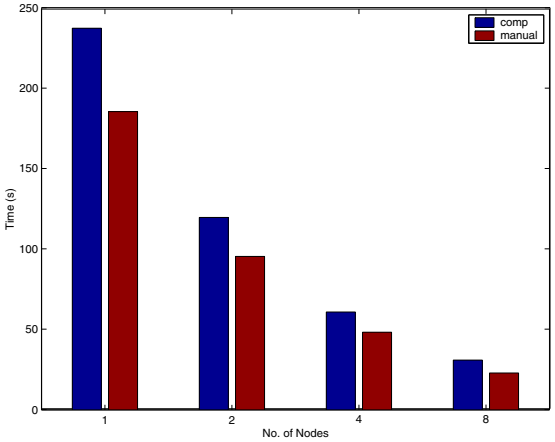

Figure 9: Performance of Apriori Association Mining: 1 GB Dataset, 1 iteration

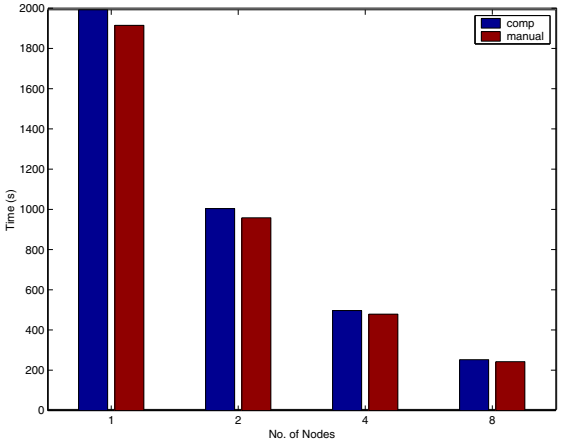

Figure 10: Performance of Apriori Association Mining: 1 GB Dataset, 2 iterations

iterations, respectively.

In apriori, the first iteration is involves very little computation and is I/O bound. Thus, we expect that the extra cost of copying will make a more significant difference in the execution time of first iteration. Figure 9 validates this conjecture. `comp` version is slower by almost 25% for the first iteration. The second iteration involves a higher level of computation. The execution times for the first two iterations combined, reported in Figure 10, show only a 5% difference in the overall performance of the two versions.

5.3 Results from k-nearest Neighbor Classifier

The last data mining algorithm we use is k-nearest neighbor classifier. Figure 11 presents experimental results from a 1 GB dataset with $k = 100$.

Since k-nearest neighbor is a relatively simple code, there is very little difference between the compiler generated and manual versions. `comp` version is consistently slower than the `manual` version, but by at most 5%.

6. RELATED WORK

To the best of our knowledge, our goal of developing compiler support for data mining algorithms is a unique one. We are not aware of any existing work or project with such a direction.

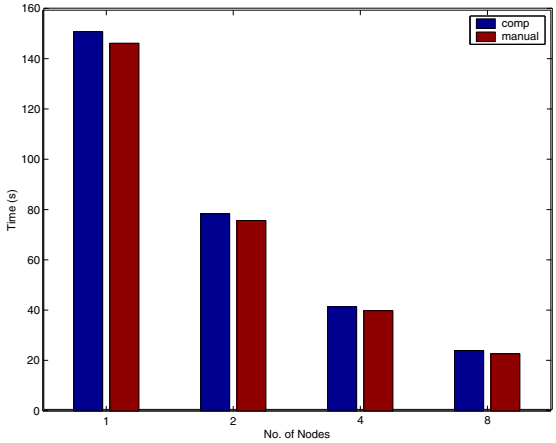

Figure 11: Performance of k-nearest neighbor classifier: 1 GB Dataset, k = 100

Our work can be considered as developing an out-of-core Java compiler. Compiler optimizations for out-of-core data-structures have been considered by several projects [7, 22, 23, 26, 27]. These projects have concentrated on stencil computations written in Fortran. Our work is different in considering a different applications class with very different communication and data access patterns, a different language, and targeting an application-class specific middleware as the compiler output.

In earlier work of Agrawal with Ferreira and Saltz, compiler techniques for supporting scientific data intensive applications written in the same dialect of Java were presented [13, 14]. In this earlier effort, a different runtime system and a different class of applications were targeted. Particularly, data mining codes involve more complicated reductions. Therefore, the global reduction analysis we have presented in this paper is much more sophisticated than the algorithm reported earlier for the same problem [14]. Some preliminary ideas towards developing compiler support for data mining were described in an earlier workshop paper [2].

Our proposed compiler work is also different from the various distributed memory compilation [1, 3, 10, 18, 28, 30] projects. We are performing parallelization of generalized reductions over disk-resident datasets, which has not been targeted by any of these projects. Several recent projects have explored the use of Java for numerical and high-performance computing [4, 12, 25, 29]. Our work is distinct in focusing on a different class of applications and performing distributed memory parallelization.

7. CONCLUSIONS

In this paper, we have described and evaluated a compiler for distributed memory parallelization of data mining codes that execute on disk-resident datasets. We have used a data parallel dialect of Java to express this class of applications. Our compiler heavily uses a middleware that we had developed in our earlier work for the same class of applications.

We have evaluated our compiler using three popular data mining algorithms, apriori association mining, k-means clustering, and k-nearest neighbors classifiers. We used disk-resident datasets for each of these three codes. Our experimental results show that 1) the compiler generated parallel data mining codes achieve high speedups in a cluster environment, 2) the performance of compiler

generated codes is quite close to the performance of manually written codes, and 3) simple additional optimizations like inlining can further reduce the gap between compiled and manual codes.
